Abstract

BACKGROUND: Acute encephalitis and encephalopathy (AEE) are life-threatening diseases in children. However, no laboratory examinations are performed for their early diagnosis and treatment. Alpha 2-macroglobulin (α 2M) is a blood glycoprotein that increases at the early stages of inflammation. In this study, we investigated whether α 2M was associated with AEE.

METHODS: We analyzed the association between AEE and α 2M using cerebrospinal fluid (CSF) and serum samples from patients with acute disseminated encephalomyelitis (ADEM), infection-related acute encephalopathy (AE), febrile status epilepticus (FSE), and febrile seizure (FS). Samples were collected in the pediatric department of hospitals throughout Fukushima Prefecture between January 1, 1999, and May 31, 2012.

RESULTS: α 2M levels in the CSF were quantified at 4.7 (3.8–8.4) μ g/mL for ADEM, 2.1 (1.1–2.3) μ g/mL for AE, 1.1 (0.9–6.4) μ g/mL for FSE, and 1.0 (0.8–1.1) μ g/mL for FS. α 2M levels in patients with ADEM were significantly higher than those in patients with AE and FS ($p = 0.019$ and $p = 0.002$, respectively). The ratio of the α 2M level in the CSF to that in the serum in patients with ADEM was significantly higher than that in patients with FSE ($p = 0.04$). In patients with ADEM, α 2M levels in the CSF decreased with treatment.

CONCLUSIONS: Our results suggest that the ratio of the α 2M level in the CSF to that in the serum reflects the neuroinflammatory status of patients with ADEM and indicates the expression of early neuroinflammation in ADEM.

Key words: Alpha 2-macroglobulin; neuroinflammation; encephalitis; encephalopathy; febrile seizure

Running title: Alpha 2-macroglobulin in ADEM

Introduction

Acute encephalitis and encephalopathy (AEE) can result in various sequelae, including death; hence, early intervention is required. Although AEE occurs with a low frequency, it is common in infants in East Asia (1). It results from various causes, including viral infections and connective tissue disease; moreover, pathologies related to immune conditions are different and have not yet been clarified. Therefore, AEE diagnosis is based on a comprehensive assessment of each patient's clinical course, laboratory examinations, head imaging, and electroencephalogram findings. However, in the acute phase, particularly when the patient is in a critical condition, diagnosis is often challenging because of the difficulty associated with conducting adequate examinations. In other words, these diseases are difficult to distinguish based on clinical presentations, despite the difference in pathologies.

Acute encephalitis is classified into viral and non-viral encephalitis. The most common viral encephalitis is herpes encephalitis, whereas the most common non-viral encephalitis types include acute disseminated encephalomyelitis (ADEM) and non-herpetic acute limbic encephalitis (ALE). In viral encephalitis, viral pathogen isolation or gene detection is directly linked to its diagnosis. The herpes simplex virus is the most common cause of encephalitis in western countries. Herpes simplex encephalitis occurs at all ages during infancy and childhood, with peak incidence during the first year of life (2). For non-viral encephalitis, diseases in which autoantibodies are involved in the pathology have recently been clarified, such as the anti-N-methyl-D-aspartic acid receptor antibody in non-herpetic ALE. Nevertheless, the pathology of ADEM remains unclear.

Acute encephalopathy (AE) is classified as being either related or unrelated to infectious diseases. Infectious disease-related AE is a generic term for a wide range of cerebral dysfunctions accompanying infectious diseases, although no finding has suggested pathogen invasion in the central nervous system (CNS). On the contrary, encephalopathy unrelated to infectious diseases is a brain dysfunction accompanying various non-infectious diseases, such as liver failure, renal failure, and hypertension. Febrile seizure (FS) is a generic term for the condition in which convulsions appear transiently during a fever. FS is a common disease in children and has a good prognosis without clinical sequelae. As the initial clinical symptoms of ADEM, AE, and FS are similar, these diseases are difficult to differentiate in the acute phase. Many cytokines and biochemical proteins have been studied as biomarkers of AEE. Reportedly, levels of inflammatory cytokines in the cerebral spinal fluid (CSF) increase during the acute phase, and studies have reported the role of interferon-gamma in acute encephalitis; the role of interleukin-6 (IL-6) and IL-8 in bacterial meningitis; and the role of tumor necrosis factor (TNF)-alpha, soluble TNF receptor-1, and IL-6 in AE (3, 4). On the contrary, regarding biochemical proteins in the CSF, S-100B, glial fibrillary acidic protein (GFAP), and tau protein

have been reported as brain injury biomarkers of AE (5–8). These biomarkers represent the repair process of damaged nerve cells and axons. Therefore, they are not suitable for expressing neuroinflammation in the acute phase.

Alpha 2-macroglobulin ($\alpha 2M$) can be an indicator of acute inflammation, which is a biological defense response, unlike the previously reported damaged substances resulting from cytotoxicity, such as S-100 B, GFAP, and tau protein. We focused on $\alpha 2M$, whose blood level increased in a short time at the onset of inflammation. An increase in $\alpha 2M$ levels in the CSF in bacterial meningitis has been reported (3, 9, 10). Extensive studies have been conducted on the relationship between $\alpha 2M$ levels in the CSF and CNS diseases in patients with bacterial meningitis, showing that $\alpha 2M$ levels in the CSF reflected $\alpha 2M$ produced in the serum during systemic inflammation due to the damage to the blood–brain barrier (BBB) (3, 10–12). However, there have been no reports on $\alpha 2M$ levels in patients with ADEM.

In this study, we aimed to measure $\alpha 2M$ levels in the CSF and serum samples of patients with ADEM, AE, febrile status epilepticus (FSE), or FS in the acute phase and to examine the association between neuroinflammation and $\alpha 2M$.

Materials and Methods

Sample collection

Participants

We analyzed preserved samples collected from 35 patients with ADEM, AE, FSE, and FS who were treated in the pediatric departments of hospitals throughout Fukushima Prefecture between January 1, 1999, and May 31, 2012. These samples were stored to assess cytokine levels and conduct viral polymerase chain reactions (PCRs). The first diagnosis was provided based on the findings on admission, and it was confirmed by the clinical course. A presumable diagnosis of ADEM was clinically made based on alterations to or a loss of consciousness lasting > 24 h, presenting with acute polysymptomatic neurological signs, and cranial/spinal imaging showing one or multiple lesions suggestive of demyelination. A presumable diagnosis of AE was clinically established based on the acute onset of impaired consciousness accompanied by brain dysfunction, usually preceded by infection (1, 13). The FS group consisted of children who presented with fever and seizures; however, they were later found to be free from acute neurological damage based on the course of clinical events, laboratory data, and brain imaging, where available. FSE was diagnosed in patients with FS who presented with seizures lasting for > 30 min. CSF samples from patients with bacterial meningitis were used as positive controls, and patients with leukemia in remission with no neurological abnormality confirmed by regular examinations were used as negative controls. Patients with viral meningitis, myelitis, or vascular, metabolic, endocrine, or toxic disorders were excluded.

Preservation of CSF and serum samples

CSF and serum samples were all collected within 24 h after disease onset. These samples were immediately centrifuged after collection and stored at -80°C . Patients who provided samples in which macroscopic hemolysis was observed were excluded from the analysis.

Ethics

Preserved samples were used in this study. This study was conducted with the approval of the Ethics Committee of the Fukushima Medical University (approval no. 1684). Information related to this research was released on our university website, and patients were included in the study using an opt-out methodology.

Immunoblotting

The protein concentration of clinical samples was quantified using a BCA Protein Assay Kit (ThermoFisher Scientific, Waltham, MA, USA). CSF samples were diluted with a sample loading buffer and heated at 95°C for 5 min, and then electrophoresed at 200 mV, 20 mA/sheet, for 73 min using a 5%–20% gradient polyacrylamide gel (Wako, Osaka, Japan). Clinical specimens with a total protein content of 0.4 μg and 2 ng of human plasma $\alpha 2\text{M}$ (Sigma-Aldrich, St. Louis, MO, USA) as a standard were electrophoresed. The gel of <15 kDa was cut out from the main gel and subjected to silver staining (Wako) to detect transthyretin as a banding control. It was then transferred to nitrocellulose membranes (Bio-Rad Laboratories, Hercules, CA, USA) at 300 V, 350 mA, for 45 min by wet western blotting. After blocking for 1 h at room temperature under 3% milk phosphate-buffered saline containing Tween-20 (PBST), the membranes were reacted with 3 $\mu\text{g}/\text{mL}$ of anti- $\alpha 2\text{M}$ antibody (ICN/Cappel, Aurora, OH, USA) and diluted with 3% milk PBST for 2 h. After washing three times with PBST, the membranes were reacted with horseradish peroxidase (HRP)-labeled anti-goat IgG antibody (Jackson ImmunoResearch Laboratories, West Grove, PA, USA), diluted to 0.08 $\mu\text{g}/\text{mL}$ with 3% milk PBST for 1 h, and then washed in the same way with PBST. Immunoreactive bands were detected using a SuperSignal® West Dura Extended Duration Substrate (ThermoFisher). The band intensity was calculated using an Image Saver 6 luminescence detector (ATTO, Tokyo, Japan).

Enzyme-linked immunosorbent assay (ELISA)

For ELISA, 100 μL of anti-human $\alpha 2\text{M}$ antibody (2.0 $\mu\text{g}/\text{mL}$; ICN/Cappel Pharmaceuticals) diluted with 0.05 M carbonate–bicarbonate (pH 9.6) was added to each well of a 96-well C8 MaxiSorp™ immunomodule plate (Nunc, Roskilde, Denmark) and incubated at 4°C overnight.

After washing once with Tris-buffered saline containing Tween-20 (TBST), 300 μ L of 10% Block Ace (DS Pharma Biomedical, Osaka, Japan) was added to each well and incubated as a blocking step for 1 h. After washing five times with TBST, 0.75 μ L of each CSF sample was applied to each well and incubated at 37°C for 1 h. After washing again five times with TBST, the plate was incubated with 100 μ L of HRP-conjugated anti-human α 2M antibody (2.0 μ g/mL; GeneTex, San Antonio, TX, USA) at room temperature for 1 h. After further washing five times with TBST, the plate was reacted with 3, 3', 5, 5'-tetramethylbenzidine peroxidase substrates (Kirkegaard and Perry Laboratories, Gaithersburg, MD, USA). The reaction was quenched using 1 M hydrochloric acid, and the absorbance at 450 nm was measured with a microplate reader (Bio-Rad Laboratories).

Immunohistochemistry

Formalin-fixed paraffin-embedded brain tissue infected with herpes encephalitis was cut into 5- μ m-thick sections using a microtome and mounted on glass slides. Deparaffinized sections were incubated with or without anti-human α 2M antibody (goat IgG, AF1938, R&D SYSTEMS) followed by biotinylated rabbit anti-goat IgG (Nichirei, Tokyo, Japan). The antigens were visualized with avidin–biotin peroxidase complex and peroxidase DAB enzyme histochemistry. Sections were then counterstained with cresyl violet and cover-slipped.

Statistical analysis

Statistical analysis was performed using IBM SPSS Statistics 21 (IBM Japan, Ltd., Tokyo, Japan). Continuous variables were expressed as medians (interquartile range). Comparisons between groups were made using the Kruskal–Wallis test. Thereafter, comparisons between two groups were made using the Mann–Whitney U test. A p-value < 0.05 was considered statistically significant.

Results

Patient characteristics

Table 1 shows the characteristics of patients according to the diagnosis. In total, 35 patients (17 boys, 48.6%, and 18 girls, 51.4%) were enrolled. The age at disease onset ranged from infancy to school aged. No significant differences were found in their age at diagnosis.

General examination findings

The number of cells in the CSF and the white blood cell count in blood, as well as the C-reactive protein (CRP) levels in the blood samples, are shown in Table 2. The median number of cells in the CSF was 41.5 (27.8–49.0)/ μ L for patients with ADEM, 2.0 (1–2.5)/ μ L for those

with AE, 1.5 (1.0–2.8)/ μ L for those with FSE, and 5.0 (1.0–7.0)/ μ L for those with FS. The number of cells in the CSF samples from patients with ADEM was significantly higher than those from patients with AE, FSE, and FS ($p = 0.02, 0.01, \text{ and } 0.04$, respectively). On the contrary, no significant differences were found in the number of cells in the white blood cell count or CRP levels among the blood samples.

Detection of α 2M in CSF by western blotting

A 180-kDa α 2M band (Fig. 1) was detected in all CSF samples from patients with AE, ADEM, FSE, and FS. Strong bands were detected in two samples (nos. 1 and 2) from patients with ADEM. Samples from patients with bacterial meningitis, in whom α 2M levels in the CSF were reported to increase markedly, were used as positive controls (no. 11). A strong band was also detected in the other sample from patients with AE, but most other samples had weak bands. In addition, the bands of the control samples were weak (nos. 9 and 10).

Quantification of α 2M in CSF and serum by ELISA

To confirm the results of the western blot analysis, we performed sandwich ELISA for α 2M using the CSF and serum samples (Table 3). The median α 2M level (interquartile range) in the CSF was 4.7 (3.8–8.4), 2.1 (1.1–2.3), 1.1 (0.9–6.4), and 1.0 (0.8–1.1) μ g/mL in patients with ADEM, AE, FSE, and FS, respectively. The α 2M level in patients with ADEM was significantly higher than those in patients with AE and FS ($p = 0.019$ and $p = 0.002$, respectively). For reference, the α 2M level in the CSF from patients with bacterial meningitis ($n = 4$) and control patients ($n = 18$) was 24.0 (6.9–25.2) and 1.54 (1.3–2.0) μ g/mL, respectively (data are not shown). On the contrary, the median α 2M level in the serum of patients was 363.9 (352.3–380.8) mg/dL in ADEM, 353.8 (328.7–429.7) mg/dL in AE, 356.4 (335.1–392.3) mg/dL in FSE, and 263.6 (174.7–284.9) mg/dL in FS. No significant differences were observed in α 2M levels in the serum among the diseases. The ratio of the α 2M level in the CSF to that in the serum was examined, and the median value of this ratio in patients with ADEM was significantly higher than those in patients with AE and FSE ($p = 0.016$ and $p = 0.04$, respectively).

Scatter diagram of α 2M levels in CSF and serum

To investigate the correlation between α 2M levels in the CSF and serum, we plotted α 2M levels in 10 paired samples of the CSF and serum from five patients with ADEM and five patients with AE (Fig. 2). α 2M levels in the CSF differed markedly among patients with ADEM, regardless of α 2M in their serum. There was almost no correlation between α 2M levels in the CSF samples and those in the serum samples ($R = 0.264, p = 0.668$) from patients with ADEM. On the contrary, in patients with AE, α 2M levels in the CSF were low.

Receiver operating characteristics (ROC) curve

To distinguish ADEM from the other diseases (AE, FSE, and FS) based on the ratio of $\alpha 2M$ levels in the CSF and in serum, ROC curve analysis was performed (Fig. 3). The $\alpha 2M$ cutoff level, according to Youden's index (sensitivity + specificity - 1), was 0.42 $\mu\text{g}/\text{mg}$. The sensitivity and specificity were 1.00 and 0.79, respectively. Furthermore, to analyze $\alpha 2M$ levels in the CSF, the cutoff level was set as 2.5 $\mu\text{g}/\text{mL}$. The sensitivity was 1.00 and specificity was 0.80, which were almost the same as those for the ratio of the $\alpha 2M$ level in the CSF and that in the serum.

Changes in $\alpha 2M$ band levels in the CSF of patients with ADEM after treatment

We examined the temporal changes in $\alpha 2M$ band levels in the CSF (Fig. 4). Compared with CSF samples obtained at disease onset, $\alpha 2M$ band levels decreased after steroid pulse therapy (no. 1 vs. no. 2 and no. 3 vs. no. 4). On the contrary, in samples obtained from a patient before being diagnosed with ADEM who did not receive therapeutic intervention, no significant decrease was found in the band levels even 10 days after disease onset (no. 5 vs. no. 6).

$\alpha 2M$ immunoreactive cells in herpes viral encephalitis

To examine $\alpha 2M$ production in the CNS, the tissue sections of patients with herpes simplex encephalitis were subjected to immunohistochemistry. As shown in Fig. 5A, astrocyte-like cells (arrow) and microglia-like cells (circle) were immunoreactive against anti- $\alpha 2M$ antibodies. Vascular endothelial cells were also immunoreactive (asterisk). Many macrophage-like cells were also immunoreactive in the perivascular Virchow–Robin spaces of blood vessels (data not shown). No immunoreactive signal was observed without the first antibody (Fig. 5B).

Discussion

$\alpha 2M$ is a glycoprotein with a molecular weight of 725.000, making it one of the most polymeric substances among the plasma proteins, and it exhibits a mass of approximately 180 kDa by electrophoresis (14). $\alpha 2M$ is produced in the Kupffer cells of the liver during the early stage of inflammation, and it appears in the blood. Regarding its function in the blood *in vivo*, $\alpha 2M$ is known to non-specifically capture proteases released from bacteria and act as a protease inhibitor, resulting in the inhibition of cellular immunity (15). $\alpha 2M$ is characterized by its rapid response, which is more rapid than antigen–antibody reactions. After capturing proteases, $\alpha 2M$ –protease complexes are taken up by $\alpha 2M$ receptors on the surfaces of hepatocytes, macrophages, fibroblasts, and mast cells. Therefore, the complexes disappear from the blood upon the resolution of the inflammation (16, 17).

In this study, $\alpha 2M$ levels in the CSF of patients with ADEM were higher than those in patients with AE, FSE, and FS (Fig. 1). $\alpha 2M$ levels in the CSF and serum from patients with bacterial meningitis showed a significantly strong correlation ($r = 0.74$, $p < 0.0001$) (3). In other words, it appears that $\alpha 2M$ in the case of bacterial meningitis is produced by the liver and that $\alpha 2M$ levels in the CSF increase as a result of the concentration gradient of $\alpha 2M$ in the serum. Kanoh et al. concluded that $\alpha 2M$ levels in the CSF of patients with bacterial meningitis increase as a result of the permeation of $\alpha 2M$ from the serum to the CSF. $\alpha 2M$ has a large molecular weight, so this permeation depends on the degree of inflammation-induced BBB damage (10). However, no studies on $\alpha 2M$ levels in the CSF of patients with ADEM have been reported. A significant difference was found in $\alpha 2M$ levels in the CSF between patients with ADEM and those with AE, whereas no significant differences were observed in serum $\alpha 2M$ levels of patients with these diseases (Table 3).

ADEM is defined as the first episode of inflammatory demyelination, with polyfocal neurological deficits implicating the involvement of multiple sites of the CNS (18). There have been no reports on vascular permeability in patients with ADEM. Furthermore, the mechanism relating to the extent of BBB damage and the concentration gradient of serum $\alpha 2M$ is yet to be elucidated. In patients with ADEM, $\alpha 2M$ levels in the CSF are not correlated with those in the serum, suggesting that $\alpha 2M$ is produced in the CNS (Fig. 2). Serum $\alpha 2M$ plays an important role as a carrier protein for IL-6 and activates IL-6 produced at local inflammatory sites (19). Our present results indicate that astrocyte-like cells may produce $\alpha 2M$ in brain tissues (Fig. 5). This observation is supported by neuroinflammation relating to a microglia–astrocyte–mast cell network (20). In addition to findings from patients with CNS infections, such as herpes simplex encephalitis, those from patients with neurodegenerative diseases, such as Alzheimer's disease, multiple sclerosis, and Parkinson's disease, also demonstrates neuroinflammation induced by glial cells of the brain (21). To date, there have been no reports on $\alpha 2M$ production in the brain. The results of our study suggest that $\alpha 2M$ is, at least partly, produced in the CNS under inflammatory conditions.

In ADEM, it is unknown whether the increase in $\alpha 2M$ is due to brain production or vascular permeability. The mechanism of neuroinflammation is related to microglia and mast cells, which act as macrophages in the brain and react with cytokines, chemokines, and neurotransmitters. When lesions form in CNS, microglia are activated to produce inflammatory cytokines and mediate inflammatory responses to disease or injury. One of these responses may be $\alpha 2M$ production.

We investigated whether $\alpha 2M$ levels in the CSF could be used clinically. $\alpha 2M$ levels in the CSF and the ratio of the $\alpha 2M$ level in the CSF to that in the serum were significantly elevated in the acute phase of ADEM. On the contrary, a comparison of the $\alpha 2M$ bands in the CSF samples

obtained at disease onset and after treatment showed that the bands were weaker after steroid pulse treatment. However, in a patient not receiving treatment, the $\alpha 2M$ bands remained strong over time (Fig. 4). Changes in $\alpha 2M$ levels in the CSF may have reflected the effect of intervention. These data suggest that the ratio of the $\alpha 2M$ level in the CSF to that in the serum reflects the neuroinflammatory status of patients with ADEM and indicates the expression of early neuroinflammation in ADEM.

Limitations

In this study, pathogens are not clearly known in any AEE cases. In addition, as our study uses only a small number of samples, further accumulation of data is warranted. Finally, the presence of $\alpha 2M$ in the CSF does not indicate disease specificity; therefore, the results should be interpreted quantitatively, considering the clinical course.

Figure legends

Fig. 1: Western blotting of CSF samples

(A) The same quantity of CSF protein (0.4 μ g) was applied to each lane. Western blotting was performed using anti-sheep α 2M antibody. Nos. 1 and 2 are for patients with ADEM, 3 and 4 are for patients with AE, 5 and 6 are for patients with FSE, and 7 and 8 for patients with FS. Migrating positions of molecular weight markers (150 and 250 kDa) are indicated by arrows (far left of the figure). The bands for leukemia in remission (nos. 9 and 10) and that for bacterial meningitis (no. 11) are shown on the far right side of the figure.

(B) Silver staining was performed and a gel < 15 kDa was used as a loading control.

α 2M, alpha 2-macroglobulin; ADEM, acute disseminated encephalomyelitis; AE, acute encephalopathy; CSF, cerebrospinal fluid; FSE, febrile status epilepticus; FS, febrile seizure.

Fig. 2: Scatter diagram of α 2M levels in the CSF and serum

α 2M levels in the CSF and serum are plotted along the vertical and horizontal axes, respectively. Closed circles represent α 2M levels in patients with ADEM and open circles represent those in patients with AE. The boxed area in the figure is the reference range of α 2M levels in the serum.

α 2M, alpha 2-macroglobulin; ADEM, acute disseminated encephalomyelitis; AE, acute encephalopathy; CSF, cerebrospinal fluid.

Fig. 3: Receiver-operator characteristic curve for the ratio of the α 2M level in the CSF to that in the serum. At a cutoff level of 0.42 μ g/mg, the sensitivity and specificity for ADEM were 1.00 and 0.79, respectively

α 2M, alpha 2-macroglobulin; ADEM, acute disseminated encephalomyelitis; CSF, cerebrospinal fluid.

Fig. 4: Changes in α 2M band levels in the CSF after treatment for ADEM

Paired samples of the CSF (on disease onset and after treatment) were obtained from patients with ADEM. Western blotting was performed in the same manner as in Fig. 1. Nos. 1 and 3 show α 2M bands at onset, and nos. 2 and 4 show their α 2M bands after steroid pulse therapy. Both α 2M levels decreased after treatment. On the contrary, there was no change in α 2M bands between nos. 5 and 6, obtained at a 10-day interval from a patient before being diagnosed with ADEM.

α 2M, alpha 2-macroglobulin; ADEM, acute disseminated encephalomyelitis; CSF, cerebrospinal fluid.

Fig. 5: α 2M immunoreactive cells in herpes simplex encephalitis

On encephalitis tissue, astrocyte-like cells (arrow) and microglia-like cells (circle) were immunoreactive against anti- α 2M antibodies (A). Vascular endothelial cells were also immunoreactive (asterisk). No immunoreactive signal was observed without the first antibody and only signals of counter staining with cresyl violet were observed (B).

Table 1: Patient Characteristics

	ADEM	AE	FSE	FS
n	5	7	12	11
Age, y, median (interquartile range)	4.4 (1.0–11.4)	2.3 (0.7–7.0)	1.1 (0.6–4.4)	2.6 (0.3–7.3)
Sex (B:G)	1:4	4:3	6:6	6:5

ADEM: acute disseminated encephalomyelitis; AE: infection-related acute encephalopathy; FSE: febrile status epilepticus; FS: Febrile seizure simplex type
 B:boys, G:girls

Table 2: CSF cells, WBC and CRP levels in serum samples

	ADEM	AE	FSE	FS
CSF cells (/μl)	41.5* (27.8–49.0)	2.0 (1.0–2.5)	1.5 (1.0–2.8)	5.0 (1.0–7.0)
WBC (/μl)	13000 (10200–15400)	10700 (8750–13750)	10900 (8300–16538)	12900 (-)
CRP (mg/dl)	0.97 (0.53–1.26)	0.16 (0.10–0.67)	0.96 (0.37–1.57)	1.2 (-)

The number of CSF samples : ADEM (n=5), AE (n=7), FSE (n=12), and FS(n=11).

The number of serum samples : ADEM (n=3), AE (n=7), FSE (n=10), and FS (n=1).

CSF cells: Cerebral spinal fluid cells; WBC: white blood cell; CRP: c-reactive protein.

All concentrations are expressed as median level (interquartile range).

*P-values (<0.05) for CSF cells are detected vs AE, FSE, and FS.

Table 3 : α 2M levels in CSF, serum, and ratio in CSF to serum

	ADEM	AE	FSE	FS
CSF (μ g/ml)	4.7 * (3.8–8.4)	2.1 (1.1–2.3)	1.1 (0.9–6.4)	1.0 (0.8–1.1)
Serum (mg/dl)	363.9 (352.3–380.8)	353.8 (328.7–429.7)	356.4 (335.1–392.3)	263.6 (174.7-284.9)
CSF/Serum (μ g/mg)	1.46 ** (0.75–2.28)	0.28 (0.27–0.34)	0.3 (0.27–0.50)	0.17 (-)

The number of CSF samples : ADEM (n=5), AE (n=7), FSE (n=12), and FS(n=11).

The number of serum samples : ADEM (n=8), AE (n=6), FSE (n=13), and FS (n=3).

The ratio in CSF to serum(CSF/Serum) : ADEM (n=5), AE (n=5), FSE (n=8), and FS (n=1).

All concentrations and ratio are expressed as median level (interquartile range).

*P-values (<0.05) for CSF cells are detected vs AE and FS.

**P-values (<0.05) for CSF cells are detected vs AE and FSE.

anti-human α 2M antibody

Fig.R 1

The specificity of anti-human alpha2M antibodies were verified by each producer. To further confirm the specificity we performed westernblot analysis. On the blot R&D antibody used for immunohistochemistry reacts a single band, which comigrates with purified alpha2M. ICN antibody used for westernblot analysis also reacts with a band comigrating with purified alpha2M. Faint signal around 60 kDa appears to be non-specific binding to albumin, which is contained at 1 microgram/mL. Combination of Cappel capture antibody and Gene Tex detection antibody were used for ELISA. The ELISA revealed that CSF contains 2 ng alpha2M/microliter, which is consistent with the signal on the blot, comparing purified alpha2M. These results suggest that the antibodies used are specific to alpha2M with minimum background signal.

the membranes were reacted with 3 μ g/ml of anti- α 2M antibody (cappel;ICN, Aurora, OH, USA)

100 μ l of HRP-conjugated anti-human α 2M antibody (2.0 μ g/ml; GeneTex, San Antonio, TX, USA)
